Eye Department, University College Hospital, London WIN 8AA, UK

The probability of an adult dying doubles every six or seven years. At the moment the progression is somewhat slower for women than for men. The ‘law’ describing the ‘nature of the function’ relating to human mortality was first reported by Gompertz in 1825. More recent studies have shown that the Gompertz ‘law’ is valid only within limits, breaking down in the upper age range. This implies the following. On the basis of the ‘law’ one would predict tentatively that there is a fixed human lifespan (a maximum length of life) of about 120 years. More recent analyses see this number only as a most probable one, with a longer longevity not being excluded. Indeed, the latest statistics on the ‘oldest old’ show a clear deviation from the Gompertz prediction: although late mortality has not yet reached theoretical predictions, perhaps because even the oldest old have included smokers and others subject to noxious environmental effects. The former concept of a maximum lifespan may have to be replaced by one of ‘maximum likelihood’. Amongst developed countries – and the longest-lived by no means include the richest in the world – the rate constant is about twice as great as amongst less developed countries, which indicates that their life expectancy, a sort of average, is almost 20 years longer than is true of the less developed countries. From a biological point of view, at least two explanations of the marked differences between populations in developed and less developed countries can be considered: either people in less developed countries age faster, or the biological variance amongst them is greater than is true of people in developed countries. Theoretical considerations and those of genetics support the second possibility. Several other indicators seem to correlate with the age-related increase in mortality. The senescence of the skin is one example, and the incidence of cataract is another. This emphasises that environmental factors need to be identified with precision if the aetiology of age-related conditions is to be understood. If the human genome is as uniform as most experts believe at present, then, for example, the much earlier age of onset of cataract in populations with some reliability mainly for Caucasian patients with angle-closure glaucoma were found to have lenses thicker than those of controls: however, an additional finding is that, in a British study, patients with angle-closure glaucoma were found to have lenses thicker than those of normal controls; however, an additional factor is that, in a British study, patients with angle-closure glaucoma were found to have lenses thicker than those of normal controls. However, in some of its associated findings, such as arcuate scotoma and an IOP>20mm. The problem faced by the epidemiologist is that these facts are known principally for developed countries, but data for the least developed ones are lacking, and, therefore, urgently required. One ignorance as regards geographical variations is not confirmed to accurate age-related variations of the most common ophthalmological conditions. More fundamentally, it extends to a knowledge of anatomical detail and relevant biological variables, which have been established with some reliability mainly for Caucasian eyes. This matter is most important for the understanding of the variation of some wide-spread conditions, and for their potential prevention or cure. For example, some twenty years ago a tentative geographical link was established between the prevalence of angle-closure glaucoma and the thickness of the eye lens. Normal Bantu have lenses around 9% thinner than similar populations in Denmark, and also a much lower prevalence of angle-closure glaucoma. Now it would be unwise to look for a gene amongst the Bantu which would protect them from glaucoma, and be lacking amongst the Danes. A more likely explanation is that the Bantu have thinner lenses than the Danes. The lower prevalence of angle-closure glaucoma is then an accidental result of an evolutionary phenomenon of the Bantu, namely a thin lens. It may be mentioned in passing that, in a British study, patients with angle-closure glaucoma were found to have lenses thicker than those of normal controls: however, an additional measurement, the reduced height of the cornea was also shown to be important. As regards lenses in Southern countries, there is much that is unknown. A great deal about age-related changes in (Caucasian) lenses is known. The most wide-spread of them, namely presbyopia, appears to be due to a number of causes. It tends to

While the changes with age of ‘British’ lenses have been studied, there are important changes in the concentration of calcium (which may be high in human cataractous lenses), and a progressive decline in glutathione which serves to maintain the transparency of the lens. But what are the concentrations and the rate of decline in ‘tropical’ lenses? Is the decline faster there, thus accounting, at least in part, for the earlier incidence of cataract in warm countries?

More fundamental considerations may play a role. Consider the pupil. This shows more fundamental considerations may play a role. Consider the pupil. This shows

The recent analysis of the anterior chamber depth amongst one type of Mongolians and its comparison with other studies (Fig. 1) provides another example. The anterior chamber is simply a space between the posterior surface of the cornea and the anterior surface of the lens. Consequently, its age-related variation indicates the relative positions of these two surfaces. All studies covering teenage young people show a maximum anterior chamber depth, most probably because the front of eye has reached its maximum dimensions. Thereafter the lens thickens and the anterior chamber depth decreases. But the lens grows fairly uniformly, whereas the anterior or chamber depth exhibits variable rates. As we move from the Belgians to the Inuit (Fig. 1) the slow-down tends to move to later ages. The original Mongolian data extend to an age of 85 years, and the slow-down changes to a measurable increase in depth both for men and women. The occurrence of myopia in the upper age groups has been reported more than once and, without corroborative evidence, it has been attributed to the presence of (incipient) cataracts, despite the customary assurance of “no known pathology.”

It is of no benefit to speculate whether the effect is due to life-style or other environmental factors, or genetic factors. But it illustrates that we lack the fundamental biological information to understand the underlying mechanisms and explain some of the age-related epithelial complications. More importantly, this ignorance inhibits serious attempts to project their prevalence in relation to currently increasing life expectancy.
